## Noise Sampling Analysis

The purpose of this analysis is to show what is the best compromise between the sampling frequency and accuracy, and to show whether or not there is a need for averaging samples to get rid of random noise. For this, a fast measurement was done for several hours, and the comparison between the different accuracies resulting from averaging the samles and their resampling (simulating reading interval) is shown

## Conclusions

As seen in the graph above, averaging throughout more than 2-2.2S in any measurement interval does not provide any further interesting information.

For a reasonable publish interval period, say, above 20S, the an optimal averaging time would be between 1.4 S and 2.2 S , being the fist achieving a target of $92 \%$ accuracy. For higher intervals, a longer averaging up until 2.2 shows improvement.

For a fast measurement interval, 1 S interval with a single shot measurement achieves the best accuracy, and also at 2 S interval with 1 S averaging.

However given the complexity of this implementation in firmware, and given that the gain for implementing this is $<2 \%$ accuracy, it is not recommended to apply this.
